Abstract. We present a methodology to augment system safety step-by-step and illustrate the approach by the definition of reusable solutions for the detection of fail-silent nodes – a watchdog and a heartbeat. These solutions can be added to real-time system designs, to protect against certain types of system failures. We use SDL as a system design language for the development of distributed systems, including real-time systems.

1 Introduction
Safety-critical systems are required to exhibit extremely low rates of critical failures. A variety of reliability measures such as hardware redundancy, time redundancy, software diversity, or recovery can be combined. Also, the functionality of a system may be reduced as a final consequence of a failure by guiding the system to a fail-operational (e.g., aircraft) or fail-safe (e.g., train) state. We define SDL design patterns and micro protocols for the detection of fail-silent nodes and to move the controlled system into a fail-safe or fail-operational state. Therefore new functionality must be added to realize those new requirements.

We have identified two different solutions. The first solution introduces the new functionality by refining the given components using existing design patterns WATCHDOG and HEARTBEAT, the second by adding available micro protocols to the system.

Both approaches support reusability and thus augment both design quality and productivity. One important difference is the architectural impact. SDL micro protocols are self-contained components that extend a system on the architectural level, without modifying the behaviour of context components. SDL design patterns can be applied on architectural level, too, but may also modify the behaviour of existing components, which requires detailed engineering knowledge. When applying patterns, the developer may also adapt functionalities and optimize certain system aspects.

In this report, we will introduce SDL design solutions to augment reliability found in safety-critical systems in a systematical way, with the purpose of reusing them in the incremental development of safety-critical systems. We define two SDL design patterns and two micro protocols for
the detection of fail-silent nodes.

2 SDL design patterns for reliable systems

2.1. SDL design patterns

Design patterns [4] are a well-known approach for the reuse of design decisions. In [1], another specialization of the design pattern concept for the development of distributed systems and communication protocols, called SDL design patterns, has been introduced. SDL design patterns combine the traditional advantages of design patterns – reduced development effort, quality improvements, and orthogonal documentation – with the precision of a formal design language for pattern definition and pattern application.

The SDL design pattern approach [6,8] consists of a pattern-based design process, a notation for the description of generic SDL fragments called PA-SDL (Pattern Annotated SDL), a template and rules for the definition of SDL design patterns, and an SDL design pattern pool. The approach has been applied successfully to the engineering and reengineering of several distributed applications and communication protocols, including the SILICON case study [8], the Internet Stream Protocol ST2+ [13], and a quality-of-service management and application functionality for CAN (Controller Area Network) [5]. Applications in industry, e.g., in UMTS Radio Network Controller call processing development, are in progress [10].

An SDL design pattern [4,6] is a reusable software artifact that represents a generic solution for a recurring design problem with SDL [12] as design language. Over a period of more than 25 years, SDL (System Design Language) has matured from a simple graphical notation for describing a set of asynchronously communicating finite state machines to a sophisticated specification technique with graphical syntax, data type constructs, structuring mechanisms, object-oriented features, support for reuse, companion notations, tool environments, and a formal semantics. These language features and the availability of excellent commercial tool environments are the primary reasons why SDL is one of the few FDTs that are widely used in industry.

When SDL patterns are applied, they are selected from a pattern pool, adapted and composed into an embedding context. The pattern pool can be seen as a repository of experience from previous projects that has been analyzed and packaged. The SDL patterns we have identified so far can be classified into five categories:

• **Architecture patterns** capture generic architectures and their refinements.
  Example: CLIENTSERVER [10]. This pattern captures a client/server architecture of a distributed system.

• **Interaction patterns** capture the interaction among peers, e.g., a set of application agents or service users.
  Example: SYNCHRONOUSINQUIRY [9]. This pattern introduces a confirmed interaction between two peers. After a trigger from the embedding context, an agent sends an inquiry and is blocked until receiving a response from the second agent.

• **Control patterns** deal with the detection and handling of errors that may result from loss, delay, or corruption of messages, or from agent failures.
  Example: LOSSCONTROL [9]. This pattern provides a generic solution for the detection and handling of message loss in the case of confirmed interactions, such as synchronous...
inquiries. If a response does not arrive before the expiry of a timer, the message is repeated (Positive Acknowledgement with Retransmission).

- **Management patterns** deal with local management issues, such as buffer creation or message addressing.
  
  Example: **BUFFERMANAGEMENT** [11]. When a signal is passed between two local processes, the signal parameters are stored into a buffer, and a buffer reference is sent. This technique has an impact on implementation efficiency, it reduces memory consumption and copying overhead. The pattern addresses the correct buffer management such that memory leaks, for instance, are avoided.

- **Interfacing patterns** replace the interaction between peers by interaction through a basic service provider. This may include segmentation and reassembly, lower layer connection management, and routing.

---

**<NAME>**

Each pattern is identified by a pattern name, which serves as a handle to describe a design problem, its solution and its consequences.

**Version:** The version of the pattern.

**Intent:** Provides a short informal description of the design problem and its solution.

**Motivation:** Example for the patterns usage without relying on the patterns definition.

**Structure:** Graphical representation of the involved (design) components and their relations (before and after applying the pattern).

**Message Scenario:** Typical behaviour related to this pattern. Complements the structural aspects.

**SDL Fragment:** Syntactical part of the design solution in PA-SDL (Pattern Annotated SDL). This part is adapted and composed when the pattern is applied. It defined the context, in which the pattern is applicable, the permitted adaptions, and the embedding into the context specification.

**Syntactical Embedding Rules:** The S.E.R. constrain the application of the pattern such that certain desirable properties are added or preserved.

**Example Application:** Illustration of the patterns application.

**Semantic Properties:** Results from the correct application of the pattern.

**Refinement:** Remarks for further redefining an applied pattern in accordance with the patterns instance.

**Cooperative Usage:** Usage together with other patterns.

**Known Uses:** Documentation of the use of the pattern.

**Checklist:** Used during a design review to prevent common errors. This list may be extended based on problems occurring during usage of the pattern.

**Figure 1:** SDL Design Pattern Template

---

1. It can be argued that these management patterns are rather low-level, as compared to the other examples. However, they have been discovered in an industrial cooperation, and capture realistic design decisions that lead to the generation of more efficient code. Furthermore, application of these patterns significantly reduces the number of design errors [11].
Example: CODEX [2]. This pattern provides a generic solution for encoding service data units (SDUs) and interface control information into protocol data units, the exchange of PDUs among specific protocol entities, and the decoding and forwarding of SDUs.

The definition of SDL design patterns supports their selection during the protocol design. As the result of the object-oriented analysis of requirements, an analysis model consisting of a UML object diagram and MSC message scenarios are built. Comparing the structure and the message scenarios of SDL design patterns against this analysis model strongly supports the selection of suitable patterns [9]. As the number of patterns in a typical pattern pool (see also [4]) is relatively small (10-30 patterns2), and with additional information contained in the pattern pool, for instance, on cooperative usage, this should be sufficient for a proper selection. The complete template for a pattern’s description is shown in Figure 1.

2.2. The design pattern **Watchdog**

The **Watchdog** pattern realizes the safety functionality called watchdog and belongs to the category of **Interaction patterns**. It describes a behaviour, that extends a given system.

The MSC in Figure 2 shows an example where the described design problem arises, which is solved by the suggested solution:

In an automatic safety device on trains (dead man’s control), an operator has to press a button periodically within a prior well defined time interval. When the operator desists from pressing the button, the automatic safety device assumes the operator is dead and stops the train, which leads the system to a *fail-safe* state in order to prevent a catastrophe, e.g., a crash at an unmanned crossing.

Figure 3 shows the graphical representation of the structural aspects of the pattern’s solution. Note that **Watchdog** either refines a component from the context or is added as a new component to the structure:

- **Trigger** is a component of the context, which provides an alive signal periodically.
- **Controller** is a component where watchdog functionality is to be added. The **WATCHDOG** pattern can either refine a component of the system or augment the system with a new component.

---

2. These figures result from practical experience. They differ substantially from the size of typical component repositories with 100s of elements. The relatively small number can be explained by the generic nature of patterns. Also, as the definition of "good" patterns is a substantial investment, only those patterns that are frequently applied should be included in the pattern pool.
Controlled System is the part of the system which is moved into a safe state, when life-sign fails to arrive.

![Figure 3: Structure of the design solution - WATCHDOG](image)

The SDL-Description of the WATCHDOG pattern is shown in Figure 4. It describes the syntactical part of the suggested design solution, which is adapted and composed when the pattern is applied. The extended finite state machine Watchdog that optionally refines Controller describes the watchdog functionality. The timer watchdogT is set for a duration of hbiW when triggered by a certain input from the context and restarted after a trigger (Figure 4 left). The trigger showing that the system is still alive can be one or more inputs or continuous signals. The duration hbiW is the timeout interval after which the system changes to a fail-safe/fail-operational state. This is done by sending one or more control signals to the controlled system (Figure 4 centre). Disabling the watchdog is also possible (Figure 4 right).

![Figure 4: SDL design pattern WATCHDOG: SDL Fragment](image)

2.3. The design pattern Heartbeat

The watchdog functionality assumes a periodic trigger in order to prevent the watchdog from sending control signals. If the system does not provide a periodic communication with an adequate interval, the Heartbeat pattern can be applied. This augments the system behaviour with the heartbeat that is periodically sent.
The following figure shows the graphical representation of the structural aspects of the patterns solution. Note that *Heartbeat* either refines a component from the context or is added as a new component to the structure:

- **Controller** is refined by *Heartbeat* and describes the system that has to be observed.
- **Watchdog** is a component realizing watchdog functionality as described in Section 2.2.

![Figure 5: Structure of the design solution - HEARTBEAT](image)

Figure 6 shows the SDL-description of the HEARTBEAT pattern. The EFSM *Heartbeat* describes the heartbeat functionality. After the initialization or an input signal (Figure 6, centre), the timer heartbeatT is set to the duration of hbiA and after the timeout one or more heartbeat_n signal is generated and propagated. Therefore **Controller** is refined by adding transitions to start and stop the heartbeat (optionally) and one to handle the heartbeatT by sending the heartbeat_n. The heartbeat_n has to be consumed by a corresponding component which realizes watchdog functionality. This signal can also be an existing signal in the system that can be used for a heartbeat.

![Figure 6: SDL design pattern HEARTBEAT](image)
3 Micro Protocols for reliable systems

3.1 SDL micro protocols

In [7], the structuring unit micro protocol, i.e. a communication protocol with a single (distributed) functionality and the required protocol collaboration, has been identified and applied to SDL designs. A functionality (e.g., flow control, loss control, QoS monitoring) is a single aspect of internal system behavior that may be distributed among a set of system agents, with causality relationships between single events. In [3], a fine-grained development process, together with a generic micro protocol framework, is presented. From a reuse viewpoint, micro protocols classify as design components, which are selected from a library and composed. Obviously, there are several ways to represent them in SDL, for instance, by specifying SDL block types, SDL process types, SDL service types, or SDL procedures. Which one to use depends on the composition of micro protocols, which in turn depends on the protocol that is to be configured.

Micro protocol definitions are organized using SDL packages. An SDL package is a collection of type definitions, and is used here to encapsulate SDL types belonging to the same micro protocol. This way, a micro protocol library can be expressed as a set of SDL packages, i.e., ready-to-use components. Also, common parts of a set of micro protocols may be extracted into a package that is imported by each micro protocol definition. Alternatively, several related micro protocols may be grouped into one package.

3.2 The micro protocol Watchdog

The micro protocol Watchdog is encapsulated in one single process type (Figure 7) and may be specialized to match the requirements of the embedding context. A timer watchdogT is used to monitor receipt of an alive signal from the context within a well-defined interval. This safelnterval is initially defined, but can be modified by redefining the virtual start transition. When Watchdog does not receive an alive signal within this given period, the timer watchdogT triggers a transition to send a signal to the context (controlled system). Again, this signal must be specified by redefining a virtual transition. Optionally, a signal may be send when the watchdog assumes the observed system to be dead and

Figure 7: Micro protocol Watchdog
an alive signal reappears.
In order to provide a periodic alive trigger, another micro protocol Heartbeat can be used.

3.3. The micro protocol Heartbeat

The micro protocol Heartbeat is used to provide a system with a periodic sending of an alive signal. This signal is used to trigger the micro protocol Watchdog showing that the observed system is still alive.

The behaviour is encapsulated in one single process type shown in Figure 8. The predefined heartbeatInterval in which signals are sent should be adapted to fit the requirements of the watchdog observing this system. This is done by refining the start transition.

![Figure 8: Micro protocol Heartbeat](image-url)
WATCHDOG

Version 1.3

Intent:
The WATCHDOG pattern realizes a safety functionality generally known as watchdog. A watchdog is a component or functionality monitoring the operation of a system by observing an alive-signal. If this signal fails, a fail operational or fail safe state has to be reached.

Motivation:
Here are some examples where the described design problem arises, which can be solved by the suggested solution.

- **Automatic safety device (dead man’s control):**
  An operator (e.g., a train conductor) has to activate periodically a button or switch in accordance with a prior well-defined time interval.

MSC AutomaticSafetyDevice
**Application with safety aspects:**
An application periodically sends an alive signal to a safety component to propagate its running state. If this signal fails to appear, the safety component has to switch to a *fail-operational* or *fail-safe* state (e.g. switch off controlled system).

**Structure:**
The following shows the graphical representation of the structural aspects of the pattern’s solution. Note that *Watchdog* not necessarily has to refine a component from the context. It is also possible to newly add this component to the structure.

*Trigger* is a component from the context, which provides a peridocal *alive* signal. It can be a button or a switch (environment) or any kind of system/component.

*Controller* is, where necessary, refined by *Watchdog* and can be, for example, some control system where watchdog functionality should be added.
**Message Scenario:**
The following shows a typical generic usage scenario between the components described above.

**MSC Watchdog**

**SDL Fragment:**
After being triggered, *Watchdog* resets its timer *watchdogT* to a given period and continues working. After receiving a timeout, *Watchdog* has to ensure, that *ControlledSystem* reaches a safe state (e.g. by sending one or more control signals). If *heartbeat* becomes active again (after a failure), *Watchdog* has to set its timer to a given period in order to resume controlling.
Syntactical Embedding Rules:

In the following, we describe how to instantiate the considered SDL fragments.

- **Watchdog:**
  - **Variants:**
    - Resolve the trigger symbols - this could result in an input symbol, conditioned input, continuous signal, or an input symbol followed by a condition symbol.
    - If no component Controller is refined (thus Watchdog is added to the structure) all symbols and states from the context have to be solved and added.
  - **Renaming:**
    - If refinement is provided, the state (set) state and the signals/variables resetTrigger, failSafeTrigger_n and heartbeat are set to the states/signals/variables of the embedding context.
    - If no refinement is provided, the state (set) state is to set to a new state, the signal/variable heartbeat is set to a signal sent by the component Trigger and the signal/variable resetTrigger is set to a new signal disabling the watchdog.
    - The signals failSafeTrigger_n are to set to suitable names of the embedding context (ControlledSystem) to reach a fail-safe/operational state.

Example Application:

Semantic Properties:
Under the Assumption that ...

(A-1) The state (set) state of Watchdog will always eventually be reached. 
Sufficient condition: state is the only state of Watchdog.

... the following Commitment holds:

(C-1) Every time resetTrigger arises, the watchdog is disabled.

(C-2) Every time a timeout arises, the timer watchdogT is not reset and suitable signals are sent to ControlledSystem.

Refinement:
No Refinement needed.

Cooperative Usage:
HEARTBEAT-Pattern

Known Uses:
C. Webel: Development and Integration of QoS Micro Protocols for Controlling an Airship via WLAN, Master Thesis, Computer Networks Group, University of Kaiserslautern, Kaiserslautern, Germany, June 2004 (in german)

Checklist
• Watchdog:
  - After receiving a trigger, watchdogT is set.
  - After receiving a timeout, watchdogT is not set.
  - For every possible heartbeat a transition has to be added.
  - For every possible resetTrigger a transition has to be added.
  - watchdogT is set to a suitable value.
  - failSafeTrigger_n is always sent after a timeout.
  - the signals failSafeTrigger_n lead to a fail-safe/operational state of the controlled component.
**HEARTBEAT**

**Version 1.0**

**Intent:**
The HEARTBEAT pattern realizes a functionality generally known as *heartbeat*.

**Motivation:**
Here are some examples where the described design problem arises, which can be solved by the suggested solution.

- **Watchdog:**
  A *heartbeat* is needed in order to send a periodic *heartbeat* signal to provide the watchdog and the system to switch to fail-safe/fail-operational state.

**Structure:**
The following shows the graphical representation of the structural aspects of the pattern's solution. Note that *Heartbeat* not necessarily has to refine a component from the context. It is also possible to newly add this component to the structure.

*Controller* is a component from the context, which has to be monitored. Therefore this component has to sent a periodic signal.

*Watchdog* is a watchdog component.
**Message Scenario:**

The following shows a typical generic usage scenario between the components described above.

**SDL Fragment:**

After being triggered by signal `enableHb`, `Heartbeat` sets its timer to a given period. After receiving a timeout, one or more signals `heartbeat_n` are sent. The generic trigger `disableHb` disables the timer `heartbeatT` and thus the component `heartbeat`.

**Syntactical Embedding Rules:**

In the following, we describe how to instantiate the considered SDL fragments.

- **Heartbeat:**
  - **Variants:**
- Resolve the trigger symbols - this could result in an input symbol, conditioned input, continuous signal, or an input symbol followed by a condition symbol.
- If no component Controller is refined (thus Heartbeat is added to the structure) all symbols and states from the context have to be solved and added.
- **Renaming:**
  - If refinement is provided, the state (set) state and the signals/variables enableHb and disableHb are set to the states/signals/variables of the embedding context.
  - If no refinement is provided, the state (set) state is to set to a new state, the signal/variables enableHb and disableHb are set to new signals send by the component Controller and the signal/variable heartbeat is set to a new signal.

**Example Application:**

**Semantic Properties:**

Under the **Assumption** that ...

(A-1) The state (set) state of Heartbeat will always eventually be reached.

**Sufficient condition:** state is the only state of Heartbeat.

... the following **Commitment** holds:

(C-1) Every time disableHb arises, heartbeatT is reset.

(C-2) Every time enableHb arises, heartbeatT is set to the default heartbeat interval.

(C-3) Every time a timeout arises, the timer heartbeatT is reset and a new heartbeat signal is sent to Watchdog.

**Refinement:**

No Refinement needed.

**Cooperative Usage:**

WATCHDOG-Pattern

**Known Uses:**

**Checklist**

- **Heartbeat:**
  - After receiving a timeout, heartbeatT is set and one or more heartbeat signals are generated.
  - For every possible enableHb a transition has to be added.
Heartbeat

- For every possible disableHb a transition has to be added.
- heartbeatT is set to a suitable value.
